Does Money Impede Convergence?

John D Hey¹ and Daniela Di Cagno²

Abstract

Inspired by Clower's conjecture that the necessity of trading through money in monetised economies might hinder convergence to competitive equilibrium, and hence, for example, cause unemployment, we experimentally investigate behaviour in markets where trading has to be done through money. In order to evaluate the properties of these markets, we compare their behaviour to behaviour in markets without money, where money cannot intervene. As the trading mechanism might be a compounding factor, we investigate two kinds of market mechanism: the *double auction*, where bids, asks and trades take place in continuous time throughout a trading period; and the *clearing house*, where bids and asks are placed once in a trading period, and which are then cleared by an aggregating device. We thus have four treatments, the pairwise combinations of non-monetised/monetised trading with double auction/clearing house. We find that: convergence is faster under non-monetised trading, implying that the necessity of using money to facilitate trade hinders convergence; that monetised trading is noisier than non-monetised trading; and that the volume of trade and realised surpluses are higher with the double auction than the clearing house. As far as efficiency is concerned, monetised trading lowers both informational and allocational efficiency, and while the double auction outperforms the clearing house in terms of allocational efficiency, the clearing house is marginally better than the double auction in terms of informational efficiency when trade is through money. Crucially we confirm the conjecture that inspired these experiments: that the necessity to use money in trading hinders convergence to competitive equilibrium, lowers realised trades and surpluses, and hence may cause unemployment.

JEL Classifications: C92, D40, E24

Keywords: clearing house mechanism, double auction mechanism, experimental markets, money, monetised trading, non-monetised trading.

Acknowledgements: The authors would like to express their gratitude to Andrea Lombardo for writing the software in Visual Studio for these experiments. We also thank LUISS for use of their purpose-built laboratory, run under the auspices of CESARE. Finally we would like to thank the Editor and three referees for invaluable comments which led to significant changes in the paper.

1. Introduction

As Clower famously said in 1967, as part of the then on-going 'Keynesian Revolution' (partly initiated by Leijonhufvud, 1968): *"Money buys goods and goods buy money; but goods do not buy goods"*. This aphorism seemed to have been forgotten as part of the demise of Keynes' ideas, but is now coming back into economists' thoughts as a consequence of recent events. The key idea is that, in money-based economies, goods cannot be bartered directly for each other; instead money has to be used as a go-between. This may interfere with convergence to equilibrium, particularly, as Clower thought, in the labour market: firms do not employ workers as they cannot see the extra sales generated by them doing so. Involuntary unemployment may result.

In Hey and Di Cagno (1998) we reported on an experiment to test Clower's conjecture, using a monetised trading market with the double auction trading mechanism. We did indeed see a departure from convergence to the competitive equilibrium, but that experiment was partial in that it did not compare the monetised trading outcome with the non-monetised trading outcome. Other factors may have been influencing our results.

One possibility is that the results may have been the consequence of the objective function imposed on our subjects (that of a utility function rather than through the use of reservation prices). Indeed our objective function (maximising a function of two variables, rather than simply maximising surplus as is usually the case) may be perceived as being more complicated for subjects to understand, and it may have been that, rather than having to trade through money, that caused the lack of convergence.

Moreover we felt that the lack of convergence might have resulted from the trading mechanism that we used, rather than from the trading through money. While, as we note later, there is a general acceptance that the double auction mechanism is robustly efficient, there are studies that show greater efficiency with other mechanisms. For example, Goeree and Lindsay (2012b) show that with what they call a 'schedule market' – in which subjects enter effectively a demand schedule – efficiency reaches 95% while with a parallel double auction market it reaches only 77%. So we

implemented additional treatments with a second mechanism – that of the clearing house³ – in which subjects enter effectively a (price, quantity) pair which are then aggregated to clear the market by the experimenter. Hence the present experiment, in which we have four treatments, with each of non-monetised trading and monetised trading paired with each of two trading mechanisms – double auction and clearing house. We shall see that our conjecture about the two market mechanisms is not confirmed by the evidence; on the other hand Clower’s conjecture is – for both mechanisms. The paper is organised as follows: in section 2, we outline Clower’s conjecture and the theoretical literature that explored his conjecture; in section 3, we discuss the issues of efficiency in markets; in section 4, we describe our experimental design; in section 5, we describe our results. Section 6 concludes.

2. Clower’s conjecture and subsequent theoretical literature

Clower’s conjecture was simple and intuitively appealing – the necessity of monetised trading might cause a lack of convergence to the competitive equilibrium. The publication of his paper sparked off a flurry of theoretical work aimed at investigating his conjecture. There is one clear and repeated conclusion from this literature: that convergence to the competitive equilibrium might not be attained. Moreover, there might be several possible equilibria, and expectations might be important. The various theoretical contributions differ in their assumptions about the market and about trading. We cannot cover all the contributions, and so concentrate on those that are relevant for our experimental design. This was as follows (we give more detail later): we had two goods in our experiment and two kinds of agents, both of which started trading with stocks of just one of the two goods. They are motivated to trade through a payoff function, which is a Cobb-Douglas function defined over the amounts of the two goods that they hold at the end of trading. In the monetised treatments they had to trade through money – which is worthless at the end of the experiment.

³ We note that this is not the same as Goeree and Lindsay’s (2102b) schedule market, though it does have some features in common.

Because of this feature, and to facilitate trade, we implemented a random stopping mechanism, for otherwise subjects might backwardly induct with, as a consequence, no trade resulting.

One of the earlier papers that followed up Clower's conjecture was that of Barro and Grossman (1971) which adopted a framework similar to ours, in that there are two goods ('labor services' and 'consumable commodities') and money. However for most of the analysis prices are fixed and the process of adjustment is not considered. They use the expression 'disequilibrium', though this should be considered as equilibrium with fixed prices. Similarly Benassy (1975) talks about Neo-Keynesian Equilibrium (or K-equilibrium) – though once again prices are fixed – finding the existence of some equilibria where the level of trade and economic activity are depressed because of the wrong exchange rate. Both these papers have centralised trading. In contrast, Kiyotaki and Wright (1989) talk about equilibria with random matching and conclude that the "equilibria are not generally Pareto optimal and that when multiple equilibria coexist they are not generally Pareto comparable." Lucas (1980), like Barro and Grossman (1971), models an economy with two goods and money, but with uncertainty (here about preferences). He concludes that "the monetary equilibrium ... will not be efficient." Ostroy and Starr (1974) start with a barter economy and then introduce money. They conclude that "in the absence of double coincidence such a trading rule [one essentially satisfying double coincidence of wants] will achieve an inefficient allocation far from competitive equilibrium". Moreover, they assert that in barter settings there exist no "plausible" trading rules (that is, rules which place limits on the ingenuity or computational capacity of traders). Shapley and Shubik (1977) adopt a game-theoretic analysis and consider the various possible non-cooperative equilibria. They conclude that "a striking feature of this kind of equilibrium is its non-optimality". This result is echoed throughout this literature.

Some recent papers consider the *adjustment process* of prices in this kind of framework; so their analyses are dynamic. Of particular relevance are the papers by Crockett *et al* (2011), Gjerstad (2013) and Goeree and Lindsay (2012a and 2012b). We are primarily interested in the differences between the four treatments, but dynamics obviously play a role since trading is repeated over a

random number of trading days. If the price adjustment process is unstable, then we have to be careful about interpreting our results. We will have more to say about this later.

3. Efficiency and market mechanisms

We implement two different market mechanisms: the double auction and the clearing house. We wanted to see if the deterioration moving from non-monetised trading to monetised trading was a special feature of the double auction. But first we must define what we mean by ‘deterioration’. Here we are referring to *efficiency*. There are several definitions of market efficiency, but we concentrate on two: *informational efficiency* and *allocational efficiency*. The former concerns convergence to the competitive price, and the latter refers to the realised gains from trade. Friedman (1993) provides an early experimental study comparing the double auction and the clearing house, though in the context of non-monetised trading. He concludes that “clearinghouse markets are as informationally efficient as double auction markets and almost as allocationally efficient”, while Cason and Friedman (2008) summarise a wealth of experimental evidence by saying that “price deviations from competitive equilibrium tend to be the smallest with the SCM [clearing house], while volume is highest in CDA [double auction]”. As we have already noted these results pertain to non-monetised trading. We are interested in seeing whether they carry over to monetised trading.

Our focus on different market mechanisms and trading rules is also relevant for policy concerns since actual financial markets are organized in such a way that can be interpreted as that both non-monetised trading and monetised trading may occur (that is, the Tokyo Stock Exchange opens when New York closes). Moreover, we can find examples of markets which use a clearing house mechanism – such as the MTS Electronic Government Bond market – whereas Stock Exchanges generally implement a double auction mechanism.

4. The Experiment

We now give more detail on the experimental design. The environment is as simple as possible, yet staying faithful to Clower's insight. There are two goods, X and Y. There are two types of traders: Type X and Type Y and there are n of each type⁴. Trading is divided up into trading days. In each day, Type X traders are endowed with a quantity \underline{x} of Good X, but none of Good Y; *mutatis mutandis* Type Y traders are endowed with none of Good X but a quantity \underline{y} of Good Y. Trade takes place through the day and the payment to each subject depends upon the amounts of the two goods they end up with at the end of the day. To be specific if a trader of either type ends the day with x of Good X and y of Good Y their payment for that day will be $10v(xy)$ in euro cents⁵. Clearly if either type of agent does not trade in any day, they end up with zero payment for that day. Goods cannot be carried over from day to day.

We had four treatments, namely each of non-monetised trading and monetised trading paired with each of double auction and clearing house. We had three sessions of each treatment (with different parameters – see later), each duplicated – giving a total of 24 sessions. We use the following notation (where the $i = 1,2,3$ refers to a particular session of that treatment):

	double auction (D)	clearing house (C)
non-monetised trading (N)	ND i	NC i
monetised trading (M)	MD i	MC i

In the non-monetised treatments, each trading day is independent of all the others and there is no money. In the monetised treatments, however, there is (experimental) money and trade must be carried out using this (experimental) money. Accordingly, in the monetised treatments, we divided up each trading day into a morning, an afternoon and an evening: in the morning the market for Good X was open and agents could buy and sell Good X using (experimental) money; in the afternoon the market for Good Y was open and agents could buy and sell Good Y using

⁴ In the experiment we put n equal to 5. We deliberately made the numbers of each type the same, and made the total number of subjects in each session sufficiently high to avoid any monopolistic possibilities.

⁵ The experiment was conducted in Italy and subjects were paid in euros. There are 100 centesimi in a euro. A euro is currently worth about £0.74 or \$1.13.

(experimental) money; in the evening accounting was done and the agents informed as to how much real money they had earned for that day. The experimental money used in the trading process had no value, however; all agents were endowed with a stock of experimental money at the beginning of the experimental session but it was worthless at the end.

There is a potential problem here however: if the subjects knew the number of trading days that the experiment would last, and if they could perform backward induction, no trade would ever take place. Since experimental money is worthless at the end of the experiment, no Type Y would want to accept any experimental money on the afternoon of the final day; as a consequence no Type X would accept any money in the morning of the final day, and so on backwards. To solve this problem, we made the number of days that the experiment lasted random. Ideally we would have preferred to have had a stationary mechanism so that the probability of any day being the final day, given that the experiment had lasted to that day, would be a fixed number, but there are two problems with this: first, subjects seem to have difficulty in understanding the mechanism (if we say the probability of the experiment finishing at the end of any day is 0.1, they get increasingly nervous at and after day 10, even though there is no need to be); second if we implement it honestly, we could end up with a session having very few days, thus giving us very few observations. We adopted a compromise: we said that the experiment would last at least 18 days, and that then and thereafter the probability would be one-half that the experiment would finish at the end of any day. In practice, 13 of the 24 sessions lasted 18 periods, 9 lasted 19 periods and 2 lasted 20 periods.

As we have already noted, we ran three different sessions of each treatment, each duplicated. These differed in terms of the \underline{x} and \underline{y} . Specifically, in sessions $i = 1$, $\underline{x} = \underline{y} = 40$; in sessions $i = 2$, $\underline{x} = 60$ and $\underline{y} = 30$; and in sessions $i = 3$, $\underline{x} = 30$ and $\underline{y} = 60$. In some of the data analysis that follows we aggregate the data for the duplicated three sessions for each treatment.

Now let us investigate the stationary equilibrium implied by this setup. We consider each day as a whole. Let us denote by p and q the (absolute) prices of Good X and Good Y. Type X subjects want to maximise $10v(xy)$ subject to $p\underline{x} = p_x + qy$; the solution to this is $x^* = \underline{x}/2$ and $y^* = (p\underline{x})/(2q)$. Type Y

subjects want to maximise $10v(xy)$ subject to $qy = px + qy$; the solution to this is $x^* = (qy)/(2p)$ and $y^* = y/2$. Given that there are equal numbers of each type, equilibrium implies that, $(px)/(2q) = y/2$, and $x/2 = (qy)/(2p)$, and hence that the relative price of Good Y in the stationary equilibrium, q/p , is equal to x/y . Thus the good relatively lower in supply is relatively higher priced. In our three sessions, this stationary equilibrium relative price of Good Y is 1 in sessions 1, 2 in sessions 2, and 0.5 in sessions 3. Our experiment is partly to see if actual relative prices converge to these. We note that in this static competitive equilibrium, the payment to any subject on any given day is given by $5v(x/y)$.

One might also be interested in a dynamic equilibrium, if the experiment is considered as dynamic⁶. Clearly, in such an equilibrium, both types of agent have to end each day with the same amount of money as they started (for otherwise one Type would be increasing their stock at the expense of the other). Now consider a subject of Type X, starting each day with an amount x of Good X (the same analysis, *mutatis mutandis*, applies to the Type Y). Let us denote by $V_t(x)$ the total expected earnings for such a subject over the lifetime of the experiment as viewed from period t . Then we have that $V_t(x) = \max\{10v(xy) + (1-p)V_{t+1}(x) + p0\}$ subject to $px = px + qy$ (since when the experiment finishes no further earnings are possible). It follows that if $V_t(x) = V(x)$ for all t , then $V(x) = \max\{10v(xy)/p\}$ subject to $px = px + qy$, and hence we get the same objective function as in the one-shot problem – and the solution is identical. The random stopping mechanism makes no difference to this equilibrium, though there may well be others.

We now give some practical detail. The experiment was carried out in the purpose-built CESARE⁷ laboratory at LUISS in Rome. It was run using software written in Visual Studio by Andrea Lombardo. Subjects were recruited from a register using ORSEE (Greiner 2004). Instructions were in Italian; an English translation can be found in the Appendix (not to be published) and [online](#) where there is further detail. The software included a calculator which enables subjects to see the real money

⁶ In a sense it is a repeated, rather than a dynamic, problem, except for the existence of – ultimately worthless – experimental money.

⁷ [CEntro Sperimentale A Roma Est](#).

earnings for any end-of-day holdings of the two goods. There were a total of 24 sessions, 6 of each treatment, with 10 subjects in each session. In any one treatment, all parameters were fixed. No communication was allowed between the subjects. After subjects arrived they were given written instructions and any questions were answered. Subjects were aware only of their endowments of the two goods and not the endowments of the other subjects in the experimental session. The experiment then started and continued until the computer randomly determined when it was over. Subjects were paid in cash and, after signing a receipt, were free to go. No subject participated in more than one session. Subjects earned on average €31.03. Different treatments lasted different amounts of time, with the monetised treatments taking longer.

A brief comment should be made about the calculation of the clearing price in the non-monetised clearing house treatment, as it differs from the usual case where trading is with money. In the usual context all buyers state a (price, quantity) pair; sellers likewise. These are aggregated into step functions in (price, quantity) space and a market-clearing price found where the step functions intersect. However, in our setup, where we have two goods, the mechanism is somewhat different: buyers state a (quantity of X, quantity of Y) pair and sellers' do likewise. The meaning is as follows. If a buyer's pair is (x, y) this means that he/she is willing to exchange *up to* x units of X in exchange for *at least* y units of Y. The same applies, *mutatis mutandis*, for the sellers. How do we find the equilibrium relative price? We cannot use step functions as neither good is money and we want to find an equilibrium relative price of Y (or of X – which is the inverse). For example if 2 units of X are exchanged for 3 units of Y, then the relative price of Y is $2/3$ or the relative price of X is $3/2$. How do we find this? There are two ways – which give the same answer. The first is to draw a graph with the quantity of X along the horizontal axis and the relative price of X on the vertical axis. In this space the supply curve is the usual kind of step function, but the demand function is different: between the horizontal steps the demand curve takes the form of a rectangular hyperbola. The same is true, *mutatis mutandis*, if one does the analysis with the quantity of Y on the horizontal axis and the relative price of Y on the vertical axis. With either analysis one finds the relative price of X (or of Y –

its inverse) and the quantities of the two goods exchanged in equilibrium. Of course, we did not explain, or need to explain, this to the subjects, though we did show them a graph of the implied demand and supply functions.

5. Results

5.1 Prices and Volumes

The key results concerning the pattern of prices during the periods of the experiment can be found in Figure 1. We should note that for each treatment and each session, there are two lines, corresponding to the duplicated sessions. Overall means and standard deviations can be found in Table 1. If we start with the conventional treatment – the non-monetised double auction, ND – we see from the top left hand graph that the relative price of Good Y converges rapidly to the theoretical predictions (1 for ND1, 2 for ND2 and 0.5 for ND3). The first of these is particularly rapid, but this may be because of some kind of focal point effect (equality of prices). This may also account for the initial stages of ND2 and ND3 – starting off around 1 before almost converging to their theoretical values; ND3 is slightly high at the end. The non-monetised clearing house, NC, in the top-right, is almost as good, though here one of the NC2 sessions is slightly above and one slightly below its theoretical value, while one of the NC3 is also above its theoretical value.

When we get on to the monetised sessions, things change. The bottom-lower graph in Figure 1 shows that prices are erratic, particularly for MD1. The mean price in MD1 is in between the mean price in MD2 and MD3, as it should be, but the mean prices in MD2 and MD3 are somewhat away from their theoretical values, and the variances are high – indicating that the trading through money is hindering convergence to equilibrium. Interestingly the monetised clearing house (in the bottom-right) is somewhat less erratic and the average price in MC1 is close to its theoretical value, while in MC2 the relative price of Good Y is below what it should be and in MC3 it is slightly above.

We suspect that the sharp upturn in the relative price of Good Y in the monetised double auction may have been a consequence of subjects getting apprehensive about the end of the experiment,

and, in particular, with Type Y subjects getting increasingly reluctant to sell (in exchange for probably worthless experimental money).

One feature that we would expect from prices being away from equilibrium is that trading volumes are different from those that we would expect. Figure 2 shows total trading volumes, expressed as a percentage of the volume in the static competitive equilibrium. Means and standard deviations are, once again, shown in Table 1. We should note that there is no reason why this measure might not be above 100% - if there is 'too much' trade.

Looking at Figure 2, we see that in the non-monetised double auction treatment, volumes are generally close to 100%. The same is true for the non-monetised clearing house, though it takes somewhat longer to get close to 100%. Things change dramatically, though, with the monetised treatments, where trading volumes are well below 100%, both for the double auction and the clearing house, though the latter is more erratic.

5.2 Dynamics

In order to shed some light on the dynamics of the price adjustment process, we present in Figure 3, scatters of the change in the relative price of Good Y ($p_t - p_{t-1}$) against the departure in the previous period of the relative price from the equilibrium relative price ($p^* - p_{t-1}$) for all three sessions of each treatment. We have 102 observations for each treatment. The fitted relationships are as follows:

non-monetised double auction:	$(p_t - p_{t-1}) = -0.0014 + .3334(p^* - p_{t-1})$	$R = .461$
monetised double auction:	$(p_t - p_{t-1}) = 0.1231 + .6616(p^* - p_{t-1})$	$R = .578$
non-monetised clearing house:	$(p_t - p_{t-1}) = 0.0000 + .1452(p^* - p_{t-1})$	$R = .295$
monetised clearing house:	$(p_t - p_{t-1}) = -0.297 + .3461(p^* - p_{t-1})$	$R = .3461$

All these indicate stability in the adjustment process for all treatments.

5.3 Payments

Average payments to subjects per period are shown in Figure 4. Summaries are also presented in Table 2. In both the Figure and the Table, we present actual payments as a percentage of the

payments in the static competitive equilibrium: these latter are €2.00 in sessions 1 and €2.12⁸ in sessions 2 and 3. It follows from the definition of these variables that the maximum the average can be in all cases is 100.

In Figure 4 it is clear that in the non-monetised double auction sessions payments to subjects are around what they should be in the static competitive equilibrium. In the non-monetised clearing house sessions payments in general were a lot lower than in the non-monetised double auction, though they were approaching the latter at the end. The same is true in the monetised treatments, where payments on average to the subjects in the clearing house treatment were lower than in the double auction. We note that payments were also slightly more erratic in the monetised double auction as compared with the non-monetised double auction. Going from non-monetised trading to monetised trading with the double auction sees a decrease in average payments to subjects, while there was only a small decrease in the average payments to subjects with the clearing house. However this analysis ignores a trend effect: with the non-monetised clearing house the trend is upwards throughout the periods of trading, almost reaching 100 by the end, while the monetised clearing house starts higher but ends up below 100 at the end.

5.4 Efficiency

Finally we present some results on efficiency in the four treatments. As we remarked in section 3, we use two measures – informational efficiency and allocational efficiency. Table 3 shows the results: 3.1 presents the results on all the data – over the first 18⁹ periods of all six sessions (where we have 108 observations in each treatment); 3.2 and 3.3 disaggregate the results into the first half and the second half of each data set (54 observations in each treatment). If we concentrate on all the data¹⁰ – 3.1 – we see that monetised trading lowers the informational and allocational efficiency

⁸ It should be noted that we chose the various endowments to make these as nearly equal across sessions to make it fair to the subjects.

⁹ Different sessions had different lengths and the shortest length was 18.

¹⁰ The *p-values* report the significance levels of the Wilcoxon rank-sum test, between the figures in the adjacent rows or columns.

for both market mechanisms, with the difference being particularly significant for allocational efficiency for the double auction. Interestingly the clearing house is marginally but not significantly more informationally efficient than the double auction in the monetised treatment. The breakdown of the data into the two halves – tables 3.2 and 3.3 – shows that informational efficiency increases for both trading types as time passes, as one would hope, but allocational efficiency falls for the double auction.

6. Conclusions

One clear message emerges from these experiments: *money hinders convergence to equilibrium*. As a consequence, realised trading volumes in the monetised treatments are lower than they would be in the static competitive equilibrium, and, of necessity, realised payments/surpluses are lower. Moreover, switching to a clearing house mechanism does not remove the inefficiencies resulting from monetised trading. However, we should note that the reduction in payments in the clearing house is much smaller than the reduction for the double auction, but mainly because the clearing house starts from a lower base. Indeed, we see markedly lower payments in the clearing house treatment than in the double auction treatment – a result different from that reported by Friedman (1993). It is not clear what caused these differences, though it should be noted that in Friedman's experiments, trading was always between a good (with a stated value) and real money; in contrast we have trading between two goods (either directly or indirectly) the value of which depended upon the combinations of the two goods. Moreover in Friedman's experiments, which used non-monetised trading, the price of the trade was always explicit, while in ours the price was implicit in terms of the ratio of the quantities.

One difficulty facing the subjects in the monetised treatments, and one which is highlighted in the theoretical literature to which we have referred in section 2, is the question of *expectations*, crucially about the value of money. It has a zero value at the (random) end of the experiment, but while the experiment is continuing, it has a value in that it facilitates the implementation of future trades. All

bidding and asking in the monetised treatments had to be done in money terms, and the whole issue of *absolute* prices for the two goods is crucial. So far, we have avoided any discussion of absolute prices – framing all our analyses in terms of *relative* prices of the two goods – but clearly this is a factor that would have influenced subjects' decisions. As the perceived end of the experiment draws nearer both sides of the market would get increasingly nervous about holding money. However, the effect of this is not clear, though it may be the case that buyers would be increasingly happy to pay more, and the sellers would be increasingly happy to ask more. Indeed we notice an increase in the absolute prices of the two goods as periods pass. But the key issue is on expectations – and these may be driven by the past behaviour of absolute prices. Thus the results that we have found may just be consequence of the subjects' response to the uncertainty about future prices. But this in turn is linked to the uncertainty about future trades – and this is the whole essence of Clower's conjecture.

The bottom line of our experiment is the finding that trading volumes, and payments, in the monetised treatments are lower than in the non-monetised treatments, and hence lower than they could/should be in the competitive equilibrium. This finding confirms Clower's conjecture: that the necessity of monetised trading may cause lack of trade, and hence, in particular, create involuntary unemployment. Money does indeed impede convergence.

CESARE

Centro di Economia Sperimentale a Roma Est

Welcome to this experiment on the economics of market decision making. The Italian Ministry of Education, MIUR, has provided the funds for the experiment. The instructions are simple, and if you follow them carefully and make good decisions, you might earn a considerable amount of money which will be paid to you in cash immediately after the end of the experiment.

INTRODUCTION

In this experiment we are going to simulate a market in which you can trade two goods – Good X and Good Y – in a sequence of (experimental) market days. Each (experimental) market day consists of a morning and an evening: in the morning the market is open and you can trade Good X for Good Y; in the evening, book-keeping is done and the amount of real money that you have earned for that particular day is calculated. Your earnings for any particular day of the experiment depend upon the amounts of the two goods with which you end up in that day. Your earnings for the entire experiment consist of the sum of the earnings on each and every day.

THE NUMBER OF DAYS THAT THE EXPERIMENT WILL LAST

The actual number of market days that the experiment will last will be determined by chance. However, there will definitely be at least 18 days in the experiment. After that point, at the end of every day that the experiment continues, the computer will generate at random a number which is either zero or one, each with probability one-half. If the number is 0 the experiment will stop at that point; if the number is 1 the experiment will continue for a further day. So the experiment will definitely last at least 18 days, but it may last for 19, or 20, or 21, or 22, ... days. The number of days that it will last is thus determined at random by the computer.

THE SUBJECTS

There are two types of subjects in this experiment: Type X subjects who are endowed with Good X each day but not with Good Y; Type Y subjects who are endowed with Good Y each day but not with Good X. Your daily endowment will be the same on each day that the experiment lasts and you will be told your daily endowment before the experiment starts.

THE MARKET

In the morning the market is open. In this market, Type X subjects (those who are endowed with Good X) are potential sellers of Good X and potential buyers of Good Y, while Type Y subjects (those who are endowed with Good Y) are potential buyers of Good X and potential sellers of Good Y.

YOUR PAYMENT

Your payment for each day of the experiment is determined by the amounts of the two goods with which you end up at the end of that day. More precisely, if you end up with a quantity x of Good X and a quantity y of Good Y you will be paid $10\sqrt{xy}$ pence. (The symbol $\sqrt{}$ indicates the square root.) For example, if you end up with 10 of Good X and 10 of Good Y you will be paid $10\sqrt{100}$ pence = 100 pence = €1.00. If you end up with 8 of Good X and 18 of Good Y you will be paid $10\sqrt{144}$ pence = 120 pence = €1.20. Note that if you end up with zero of either good you will be paid nothing. As noted already, your payment for the experiment as a whole is the sum of the payments for each of the days that the experiment has lasted.

Please note that you cannot carry stocks of the goods over from one day to the next.

THE TRADING MECHANISM

The trading mechanism used in this experiment is what is called the *double auction mechanism*. Do not worry if you have not encountered this before – it is easy to understand. It is a continuous process, with trading taking place continuously throughout the trading period. At any time during the trading period Type X subjects (those endowed with Good X) can make a *bid* consisting of a quantity of Good X and a quantity of Good Y – (q_x, q_y) , while Type Y subjects (those endowed with Good Y) can similarly make a *bid* consisting of a quantity of Good X and a quantity of Good Y – (q_x, q_y) . While these look the same, the interpretation is different. For a Type X subject a bid (q_x, q_y) means that that subject is willing to offer up to q_x units of Good X in exchange for at least q_y units of Good Y. For a Type Y subject a bid (q_x, q_y) means that that subject is willing to offer up to q_y units of Good Y in exchange for at least q_x units of Good X. We note that only integer values are allowed for the quantities in the bids. Obviously sellers must hold the number of units that they wish to sell. Any such bids will be posted on all screens for all subjects to see. At any time, subjects can accept all or part of any posted bid. Partial acceptance by a Type Y subject of a bid (q_x, q_y) posted by a Type X subject means that the Type Y subject is willing to supply up to q_y units of Good Y accepting in exchange units of Good X at the rate q_x/q_y . Similarly, partial acceptance by a Type X subject of a bid (q_x, q_y) posted by a Type Y subject means that the Type X subject is willing to supply up to q_x units of Good X accepting in exchange units of Good Y at the rate q_y/q_x . After acceptance or partial acceptance, the good is traded and accounts adjusted by the computer. This bidding, asking and acceptance process continues throughout the trading period, which lasts for 4 minutes each day.

ACCOUNTING

As we have already noted: each subject will be told how many units of the two goods that they have traded; the computer will carry out the appropriate book-keeping. At the end of each day you will be told how many units of the two goods you have ended up with and the earnings implied by these amounts.

PRACTICE SESSIONS

In order that you fully understand the experiment, you will be allowed two practice days before the experiment proper starts. The earnings you get in these practice days will not count towards your earnings.

TIMEKEEPING

Each market session will last four minutes. A clock on all subjects' screens in the top right hand corner of the screen will display the time left (in minutes and seconds) to the end of that particular session. You will always know how much time is left at any point.

OTHER

If you are unsure about any aspect of this experiment please ask one of the experimenters. We hope you find it fruitful.

Welcome to this experiment on the economics of market decision making. The Italian Ministry of Education, MIUR, has provided the funds for the experiment. The instructions are simple, and if you follow them carefully and make good decisions, you might earn a considerable amount of money which will be paid to you in cash immediately after the end of the experiment.

INTRODUCTION

In this experiment we are going to simulate a market in which you can trade two goods – Good X and Good Y – in a sequence of (experimental) market days. Each (experimental) market day consists of a morning and an evening: in the morning the market is open and you can trade Good X for Good Y; in the afternoon, book-keeping is done and the amount of real money that you have earned for that particular day is calculated. Your earnings for any particular day of the experiment depend upon the amounts of the two goods with which you end up in that day. Your earnings for the entire experiment consist of the sum of the earnings on each and every day.

THE NUMBER OF DAYS THAT THE EXPERIMENT WILL LAST

The actual number of market days that the experiment will last will be determined by chance. However, there will definitely be at least 18 days in the experiment. After that point, at the end of every day that the experiment continues, the computer will generate at random a number which is either zero or one, each with probability one-half. If the number is 0 the experiment will stop at that point; if the number is 1 the experiment will continue for a further day. So the experiment will definitely last at least 18 days, but it may last for 19, or 20, or 21, or 22, ... days. The number of days that it will last is thus determined at random by the computer.

THE SUBJECTS

There are two types of subjects in this experiment: Type X subjects who are endowed with Good X each day but not with Good Y; Type Y subjects who are endowed with Good Y each day but not with Good X. Your daily endowment will be the same on each day that the experiment lasts. You will be told your Type and your daily endowment before the experiment starts.

THE MARKET

In the morning the market is open. In this morning market, Type X subjects (those who are endowed with Good X) are potential sellers of Good X and potential buyers of Good Y, while Type Y subjects (those who are endowed with Good Y) are potential buyers of Good X and potential sellers of Good Y.

YOUR PAYMENT

Your payment for each day of the experiment is determined by the amounts of the two goods with which you end up at the end of that day. More precisely, if you end up with a quantity x of Good X and a quantity y of Good Y you will be paid $10\sqrt{xy}$ pence. (The symbol $\sqrt{}$ indicates the square root.) For example, if you end up with 10 of Good X and 10 of Good Y you will be paid $10\sqrt{100}$ pence = 100 pence = €1.00. If you end up with 8 of Good X and 18 of Good Y you will be paid $10\sqrt{144}$ pence = 120 pence = €1.20. Note that if you end up with zero of either good you will be paid nothing. As noted already, your payment for the experiment as a whole is the sum of the payments for each of the days that the experiment has lasted.

Please note that you cannot carry stocks of the goods over from one day to the next.

THE TRADING MECHANISM

The trading mechanism used in this experiment is what is called the *clearing house mechanism*. Do not worry if you have not encountered this before – it is easy to understand. Type X subjects – those who are endowed with Good X – are asked to make a bid consisting of a quantity of Good X and a quantity of Good Y – (q_x, q_y) . Similarly Type Y subjects – those who are endowed with Good Y – are asked to make a bid consisting of a quantity of Good X and a quantity of Good Y – (q_x, q_y) . The Type X's bid will be interpreted to mean that this subject is willing to trade at most q_x units of Good X in exchange for at least q_y units of Good Y; if a Type X subject does not want to trade, then no bid should be entered. The Type Y's bid will be interpreted to mean that this subject is willing to trade at most q_y units of Good Y in exchange for at least q_x units of Good X; if a Type Y subject does not want to trade, then no bid should be entered. We note that only integer values are allowed for the quantities in the bids. Of course, sellers must actually have the units of the good they are intending to sell. There is a pre-determined time for entering bids and asks, and the computer will display the remaining time. If a subject does not enter a bid, the computer will interpret this as the subject not wanting to trade. When the time has elapsed, the computer will calculate the equilibrium exchange rate between the two goods and the traded quantities in the market. The equilibrium exchange rate will be determined as the exchange rate at which the quantities offered for sale are equal to the quantities demanded for purchase, for both goods. The computer will then inform each subject of the amounts they have bought and the amounts of the other good that they have sold. It is important to note: (1) that a buyer may not be able to buy all the quantity he or she bid for if the implicit exchange rate in the bid is lower than the equilibrium exchange rate or the quantity offered by the sellers is not sufficiently high; (2) that a buyer may pay less than the number of units offered if the equilibrium exchange rate is lower than the exchange rate in the bid; (3) that a seller may not be able to sell all the quantity he or she offered if the exchange rate implicit in the bid is higher than the equilibrium exchange rate or if the quantity demanded by the buyers is not sufficiently high; (4) that a seller may get more than the number of units asked for if the equilibrium exchange rate is higher than the exchange rate implicit in the bid. We note that the equilibrium prices and quantities will be integers.

ACCOUNTING

As we have already noted: each subject will be told how many units of the two goods that they have traded. The computer will carry out the appropriate book-keeping. At the end of each day you will be told how many units of the two goods you have ended up with and the earnings implied by these amounts.

PRACTICE SESSIONS

In order that you fully understand the experiment, you will be allowed two practice days before the experiment proper starts. The earnings you get in these practice days will not count towards your earnings.

TIMEKEEPING

Each market session will last four minutes. A clock on all subjects' screens in the top right hand corner of the screen will display the time left (in minutes and seconds) to the end of that particular session. You will always know how much time is left at any point. If you do not enter a bid during the time allowed, your bid will be taken to be zero.

OTHER

If you are unsure about any aspect of this experiment please ask one of the experimenters. We hope you find it fruitful.

Welcome to this experiment on the economics of market decision making. The Italian Ministry of Education, MIUR, has provided the funds for the experiment. The instructions are simple, and if you follow them carefully and make good decisions, you might earn a considerable amount of money which will be paid to you in cash immediately after the end of the experiment.

INTRODUCTION

In this experiment we are going to simulate two markets in which you can buy or sell two goods – Good X and Good Y – in a sequence of (experimental) market days. Each (experimental) market day consists of a morning, an afternoon and an evening: in the morning the market for Good X is open and you can buy or sell Good X using (experimental) money; in the afternoon the market for Good Y is open and you may buy or sell Good Y using (experimental) money; in the evening, book-keeping is done and the amount of real money that you have earned for that particular day is calculated. Your earnings for any particular (experimental) day of the experiment depend upon the amounts of the two goods with which you end up in that day. Your earnings for the entire experiment consist of the sum of the earnings on each and every day. *The actual experimental money used to facilitate trade during the experiment becomes worthless at the end of it.*

THE NUMBER OF DAYS THAT THE EXPERIMENT WILL LAST

The actual number of market days that the experiment will last will be determined by chance. However, there will definitely be at least 18 days in the experiment. After that point, at the end of every day that the experiment continues, the computer will generate at random a number which is either zero or one, each with probability one-half. If the number is 0 the experiment will stop at that point; if the number is 1 the experiment will continue for a further day. So the experiment will definitely last at least 18 days, but it may last for 19, or 20, or 21, or 22, ... days. The number of days that it will last is thus determined at random by the computer.

THE SUBJECTS

There are two types of subjects in this experiment: Type X subjects who are endowed with Good X each day but not with Good Y; Type Y subjects who are endowed with Good Y each day but not with Good X. Your daily endowment will be the same on each day that the experiment lasts and you will be told your daily endowment before the experiment starts. In addition all subjects are endowed *at the beginning of the experiment* with some experimental money: this is to facilitate trade only and becomes worthless at the end of the experiment.

THE MARKETS

In the morning the market for Good X is open. In this morning market, Type X subjects (those who are endowed with Good X) are potential sellers of the good while Type Y subjects (those who are endowed with Good Y) are potential buyers of the good. In the afternoon the market for Good Y is open. In this afternoon market, Type X subjects (those who are endowed with Good X) are potential buyers of the good while Type Y subjects (those who are endowed with Good Y) are potential sellers of the good. The trading rules are described below.

YOUR PAYMENT

Your payment for each day of the experiment is determined by the amounts of the two goods with which you end up at the end of that day. More precisely, if you end up with a quantity x of Good X and a quantity y of Good Y you will be paid $10\sqrt{xy}$ pence. (The symbol $\sqrt{}$ indicates the square root.) For example, if you end up with 10 of Good X and 10 of Good Y you will be paid $10\sqrt{100}$ pence = 100 pence = €1.00. If you end up with 8 of Good X and 18 of Good Y you will be paid $10\sqrt{144}$ pence = 120 pence = €1.20. Note that if you end up with zero of either good you will be paid nothing. As noted already, your payment for the experiment as a whole is the sum of the payments for each of the days that the experiment has lasted.

Please note that you cannot carry stocks of the goods over from one day to the next - experimental money alone can be held from one day to the next.

THE TRADING MECHANISM

The trading mechanism used in this experiment is what is called the *double auction mechanism*. Do not worry if you have not encountered this before – it is easy to understand. It is a continuous process, with trading taking place continuously throughout the trading period. At any time during the trading period potential buyers can make a *bid* consisting of a price and a quantity – (p,q) – and potential sellers can make an *ask* consisting also of a price and a quantity – (p,q) . A **bid** (p,q) means that that buyer is willing to pay up to a price p for up to q units of the good. Likewise, an **ask** (p,q) means that the seller is willing to accept any price down to p for up to q units of the good. We note that only integer values are allowed for the prices and quantities in the bids and asks. Obviously sellers must hold the number of units that they wish to sell and buyers must have the experimental money necessary to pay for the bid (namely pq). Any such bids and asks will be posted on all screens for all traders to see. At any time, buyers can accept all or part of any posted ask and sellers can accept all or part of any posted bid. Partial acceptance of a bid (p,q) by some seller means that the seller will sell *up to* q units of the good at the price p . Similarly partial acceptance of an ask (p,q) by some buyer means that the buyer will buy *up to* q units of the good at the price p . After acceptance or partial acceptance, the good is traded and accounts adjusted by the computer. This bidding, asking and acceptance process continues throughout the trading period.

ACCOUNTING

As we have already noted: each buyer will be told how many units they have bought and the prices that they paid at the end of each market; each seller will be told how many units they have sold and the prices that they received at the end of each market; The computer will carry out the appropriate book-keeping. At the end of each day you will be told how many units of the two goods you have ended up with and the earnings implied by these amounts, and the amount of experimental money with which you end up the day.

PRACTICE SESSIONS

In order that you fully understand the experiment, you will be allowed two practice days before the experiment proper starts. The earnings you get in these practice days will not count towards your earnings. Your endowment of experimental money will be put back to its original amount at the end of the practice days and before the experiment proper starts.

TIMEKEEPING

Each market session (morning and afternoon) will last four minutes. A clock on all subjects' screens in the top right hand corner of the screen will display the time left (in minutes and seconds) to the end of that particular session. You will always know how much time is left at any point.

OTHER

If you are unsure about any aspect of this experiment please ask one of the experimenters. We hope you find it fruitful.

Welcome to this experiment on the economics of market decision making. The Italian Ministry of Education, MIUR, has provided the funds for the experiment. The instructions are simple, and if you follow them carefully and make good decisions, you might earn a considerable amount of money which will be paid to you in cash immediately after the end of the experiment.

INTRODUCTION

In this experiment we are going to simulate two markets in which you can buy or sell two goods – Good X and Good Y – in a sequence of market days. Each market day consists of a morning, an afternoon and an evening: in the morning the market for Good X is open and you can buy or sell Good X using (experimental) money; in the afternoon the market for Good Y is open and you may buy or sell Good Y using (experimental) money; in the evening, book-keeping is done and the amount of real money that you have earned for that particular day is calculated. Your earnings for any particular day of the experiment depend upon the amounts of the two goods with which you end up in that day. Your earnings for the entire experiment consist of the sum of the earnings on each and every day. *The actual experimental money used to facilitate trade during the experiment becomes worthless at the end of it.*

THE NUMBER OF DAYS THAT THE EXPERIMENT WILL LAST

The actual number of market days that the experiment will last will be determined by chance. However, there will definitely be at least 18 days in the experiment. After that point, at the end of every day that the experiment continues, the computer will generate at random a number which is either zero or one, each with probability one-half. If the number is 0 the experiment will stop at that point; if the number is 1 the experiment will continue for a further day. So the experiment will definitely last at least 18 days, but it may last for 19, or 20, or 21, or 22, ... days. The number of days that it will last is thus determined at random by the computer.

THE SUBJECTS

There are two types of subjects in this experiment: Type X subjects who are endowed with Good X each day but not with Good Y; Type Y subjects who are endowed with Good Y each day but not with Good X. Your daily endowment will be the same on each day that the experiment lasts. You will be told your Type and your daily endowment before the experiment starts. In addition all subjects are endowed *at the beginning of the experiment* with some experimental money: this is to facilitate trade only and becomes worthless at the end of the experiment.

THE MARKETS

In the morning the market for Good X is open. In this morning market, Type X subjects (those who are endowed with Good X) are potential sellers of the good while Type Y subjects (those who are endowed with Good Y) are potential buyers of the good. In the afternoon the market for Good Y is open. In this afternoon market, Type X subjects (those who are endowed with Good X) are potential buyers of the good while Type Y subjects (those who are endowed with Good Y) are potential sellers of the good. The trading rules are described below.

YOUR PAYMENT

Your payment for each day of the experiment is determined by the amounts of the two goods with which you end up at the end of that day. More precisely, if you end up with a quantity x of Good X and a quantity y of Good Y you will be paid $10\sqrt{xy}$ pence. (The symbol $\sqrt{}$ indicates the square root.) For example, if you end up with 10 of Good X and 10 of Good Y you will be paid $10\sqrt{100}$ pence = 100 pence = €1.00. If you end up with 8 of Good X and 18 of Good Y you will be paid $10\sqrt{144}$ pence = 120 pence = €1.20. Note that if you end up with zero of either good you will be paid nothing. As noted already, your payment for the experiment as a whole is the sum of the payments for each of the days that the experiment has lasted.

Please note that you cannot carry stocks of the goods over from one day to the next - experimental money alone can be held from one day to the next.

THE TRADING MECHANISM

The trading mechanism used in this experiment is what is called the *clearing house mechanism*. Do not worry if you have not encountered this before – it is easy to understand. Buyers are asked to make a bid consisting of a price and a quantity – (p,q) . Sellers are asked to make an ask consisting also of a price and a quantity – (p,q) . The buyer's bid will be interpreted to mean that the buyer is willing to buy up to the stated quantity at no more than the stated price; if a buyer does not want to buy at any price, then no bid should be entered. The seller's ask will be interpreted to mean that the seller is willing to sell up to the stated quantity at no less than the stated price; if a seller does not want to sell at any price, no ask should be entered. We note that only integer values are allowed for the prices and quantities in the bids and asks. Of course, buyers must have the (experimental) money with which to finance the purchase; likewise sellers must actually have the units of the good they are intending to sell. There is a pre-determined time for entering bids and asks, and the computer will display the remaining time. If a buyer does not enter a bid, the computer will interpret this as the buyer being unwilling to buy at any price. If a seller does not enter an ask, the computer will interpret this as the seller being unwilling to sell at any price. When the time has elapsed, the computer will calculate the equilibrium price and the traded quantity in the market. The equilibrium price will be determined as the price at which the quantities offered for sale are equal to the quantities demanded for purchase. The computer will then inform each buyer of the amounts they have bought and the price which they paid and will inform each seller of the amounts they have sold and the price which they received. It is important to note: (1) that a buyer may not be able to buy all the quantity he or she bid for if the price in the bid is lower than the equilibrium price or the quantity offered by the sellers is not sufficient; (2) that a buyer may pay less than the price in the bid if the equilibrium price is lower than the price in the bid; (3) that a seller may not be able to sell all the quantity he or she asked for if the price in the ask is higher than the equilibrium price or the quantity demanded by the buyers is not sufficient; (4) that a seller may get more than the price in the ask if the equilibrium price is higher than the price in the ask. We note that the equilibrium prices and quantities will be integers. Occasionally there will be more than one equilibrium price; in such cases the computer will choose one of these at random.

ACCOUNTING

As we have already noted: each buyer will be told how many units they have bought and the price that they paid at the end of each market; each seller will be told how many units they have sold and the price that they received at the end of each market. The computer will carry out the appropriate book-keeping. At the end of each day you will be told how many units of the two goods you have ended up with and the earnings implied by these amounts, and the amount of experimental money with which you end up the day.

PRACTICE SESSIONS

In order that you fully understand the experiment, you will be allowed two practice days before the experiment proper starts. The earnings you get in these practice days will not count towards your earnings.

Your endowment of experimental money will be put back to its original amount at the end of the practice days.

TIMEKEEPING

Each market session (morning and afternoon) will last four minutes. A clock on all subjects' screens in the top right hand corner of the screen will display the time left (in minutes and seconds) to the end of that particular session. You will always know how much time is left at any point. If you do not enter a bid or ask during the time allowed, your bid or ask will be taken to be zero

OTHER

If you are unsure about any aspect of this experiment please ask one of the experimenters. We hope you find it fruitful.
